

## Topological quantum devices: a review

Cite this: *Nanoscale*, 2023, **15**, 12787 Kyung-Hwan Jin,  <sup>a</sup> Wei Jiang,  <sup>b</sup> Gurjyot Sethi<sup>†c</sup> and Feng Liu<sup>\*c</sup>

The introduction of the concept of topology into condensed matter physics has greatly deepened our fundamental understanding of transport properties of electrons as well as all other forms of quasi particles in solid materials. It has also fostered a paradigm shift from conventional electronic/optoelectronic devices to novel quantum devices based on topology-enabled quantum device functionalities that transfer energy and information with unprecedented precision, robustness, and efficiency. In this article, the recent research progress in topological quantum devices is reviewed. We first outline the topological spintronic devices underlined by the spin-momentum locking property of topology. We then highlight the topological electronic devices based on quantized electron and dissipationless spin conductivity protected by topology. Finally, we discuss quantum optoelectronic devices with topology-redefined photo-excitation and emission. The field of topological quantum devices is only in its infancy, we envision many significant advances in the near future.

### 1. Introduction

The concept of topology was first introduced into condensed matter physics in the early 80s of the last century to explain the quantum Hall effect (QHE).<sup>1</sup> It was shown that quantized electronic conductivity can result from non-trivial electronic band topology. This has not only revolutionized our fundamental understanding of electronic transport behavior, but also afforded new device concepts with the highest possible precision, *i.e.*, measurement of fine-structure of atoms, because the quantized conductivity depends on only fundamental physical constants ( $e$ ,  $h$ ,  $\pi$ ).<sup>2</sup> However, a super high magnetic field and extremely low temperature required for the QHE limited its further applications, until the concept of topology was introduced in lattice models<sup>3</sup> and solid-state materials.<sup>4–6</sup>

Over the past 18 years or so, the understanding of topological concept in condensed matters is significantly advanced along with the continued discovery of various topological materials<sup>7–11</sup> (see Fig. 1). As a new type of “quantum conductor”, 2D/3D topological insulator (TI) is a bulk insulator but an edge/surface conductor, where the edge/surface conductance is quantized, in accordance with a bulk-boundary correspondence protected by a nontrivial  $Z_2$  topology of bulk electronic

wave functions.<sup>7</sup> A TI can be viewed as two copies of Chern insulator,<sup>12</sup> one for each spin channel. Their nontrivial topology is characterized with a non-zero  $Z_2$  ( $\pm 1$ ) invariant or integer Chern number for one spin channel, which can be calculated by integration of Berry curvature of wave functions<sup>7</sup> over the Brillouin zone (BZ) for all the occupied bands below the topological gap. On the other hand, a topological Dirac/Weyl semimetal is a weak topological non-magnetic/magnetic bulk conductor with a vanishing density of states (DOS) at the Fermi level, where the Dirac and Weyl points represent a Berry flux center, *i.e.*, a divergent point of Berry curvature for the valence (conduction) bands below (above) the Dirac/Weyl point having opposite chirality (opposite pseudospin), such as the upper (lower) Dirac cones of graphene. In general, a TI can arise from gap opening at the Dirac point or band inversion of a narrow-gap semiconductor featured with two band-edge states of opposite parity (such as s- and p-states), induced by spin-orbit coupling (SOC).<sup>13–15</sup> Another prominent feature of 2D/3D TI is that their topological edge/surface states (TSSs) is helical, exhibiting a spin-momentum locking property due to SOC, which constrains the orientation of spins perpendicular to that of momenta.<sup>16,17</sup>

Also, the topological concept has also been extended to topological crystalline insulator<sup>18,19</sup> and high-order TI,<sup>20,21</sup> for which the nontrivial topology and bulk-boundary correspondence arise from protection of crystalline spatial symmetry.<sup>8,22</sup> Furthermore, the single-particle concept of topology has been incorporated into correlated materials<sup>23–25</sup> and superconductors.<sup>26–29</sup> It has been shown that topological phenomena can also emerge in collective excitations, such as phonons,<sup>30,31</sup> magnons,<sup>32</sup> and plasmons.<sup>33</sup> On the other hand,

topological flat band (FB) presents another topological manifestation, in analogy to Landau level which is topological without band inversion; while a singular band touching point between a FB and a dispersion band can be viewed as a Berry flux center, in analogy to a Dirac point.<sup>11,34–37</sup> Remarkably, the FB is dispersionless whose single-particle energy  $E(\mathbf{k})$  is independent of momentum  $\mathbf{k}$ , so that the kinetic energy is completely quenched in the FB. Consequently, this macroscopically degenerate quantum-mechanical state is inherently a strongly correlated state, offering an ideal platform to investigate exotic many-body quantum phenomena in association with topology,<sup>11</sup> such as fractional quantum Hall effect,<sup>38–40</sup> ferromagnetism,<sup>41–44</sup> Wigner crystallization,<sup>45,46</sup> superconductivity,<sup>47–49</sup> excitonic insulator<sup>50</sup> and Bose–Einstein condensates (BEC).<sup>51–53</sup> Very interestingly, a new class of quantum semiconductors have been recently proposed, which have both a flat valence and conduction bands around the Fermi level, the so-called yin-yang FB of opposite chirality.<sup>50,54</sup> In contrast with conventional semiconductors having parabolic band edges, yin-yang FBs are inherently topologically nontrivial and invoking strong electron–electron interaction, so that transport of fermionic carriers of electrons and holes, as well as bosonic excitons are quantum by nature. Such quantum semiconductors are expected to revive the “classical” semiconductor physics, leading to a paradigm shift of electronic and optoelectronic devices into the realm of quantum information and computation technologies.

Excitingly, the rise of topological materials opens a new door to topology-enabled quantum devices. It not only provides a new knob to manipulate the electronic states in conventional electronic, optoelectronic, and spintronic device settings, but has also fostered new quantum device concepts and platforms with unprecedented precision, robustness, and efficiency. For example, robust quantized conductivity renders transport signal with extremely high precision.<sup>55</sup> The spin-momentum locking property prohibits elastic backscattering allowing creation of pure quantized spin current without heat dissipation.<sup>56,57</sup> Topological superconductivity opens a new paradigm of fault-tolerant quantum computing.<sup>58</sup> As theoretical predictions of many topological phenomena have been characterized and confirmed experimentally, using transport measurement, scanning tunnelling microscopy/spectroscopy, angle-resolved photoemission spectroscopy, and magneto-optical spectroscopy, significant efforts have also been made toward realizing topological quantum devices.

In this review, we recap the recent progress made in developing topological devices, by employing new topology-enabled physical phenomena as well as engineering approaches to manipulate these phenomena. We first discuss new physical concepts and applications in association with topological spintronic devices. Specifically, we will review works in charge-spin conversion, spin transport devices, and magnetic devices enabled by unique topological properties. We then discuss recent studies to extend application of topological materials to

electronic devices, such as topological field-effect transistor and topological p–n junction. In addition, we briefly review the important role played by topology in optoelectronic device applications. In particular, we will introduce a new class of plasmonic topological materials, with promising applications in topological laser, and novel optoelectronic device employing topological FB systems.

## 2. Topological spintronic devices

In this section, we attempt to give an up-to-date overview of the research progress made in the fundamental physics and applications for topological spintronic devices. Spintronics has emerged as a promising field for advancing next-generation quantum devices with enhanced memory, processing capabilities, and reduced power consumption. These devices leverage the spin degree of freedom of electrons and/or holes, which can interact with their orbital moments. Traditionally, spin polarization in such devices is achieved through the use of magnetic layers as spin-polarizers or analyzers, or through the influence of SOC. However, by harnessing the unique topological properties of materials, it becomes feasible to create an intrinsic spin-polarized channel without magnetic fields or magnetic materials. In addition, the topologically protected spin channel allows for a long spin lifetime and spin diffusion length, which are useful in spin transistor and logic device applications. Recently, beyond the topological properties of electronic structure, new topological behaviors related to the topology of atomic structure, such as the dislocations and the nonsymmorphic crystal symmetry, are discovered. New forms of the SOC effect in specific atomic structure provide more effective means to manipulate spin transport properties.

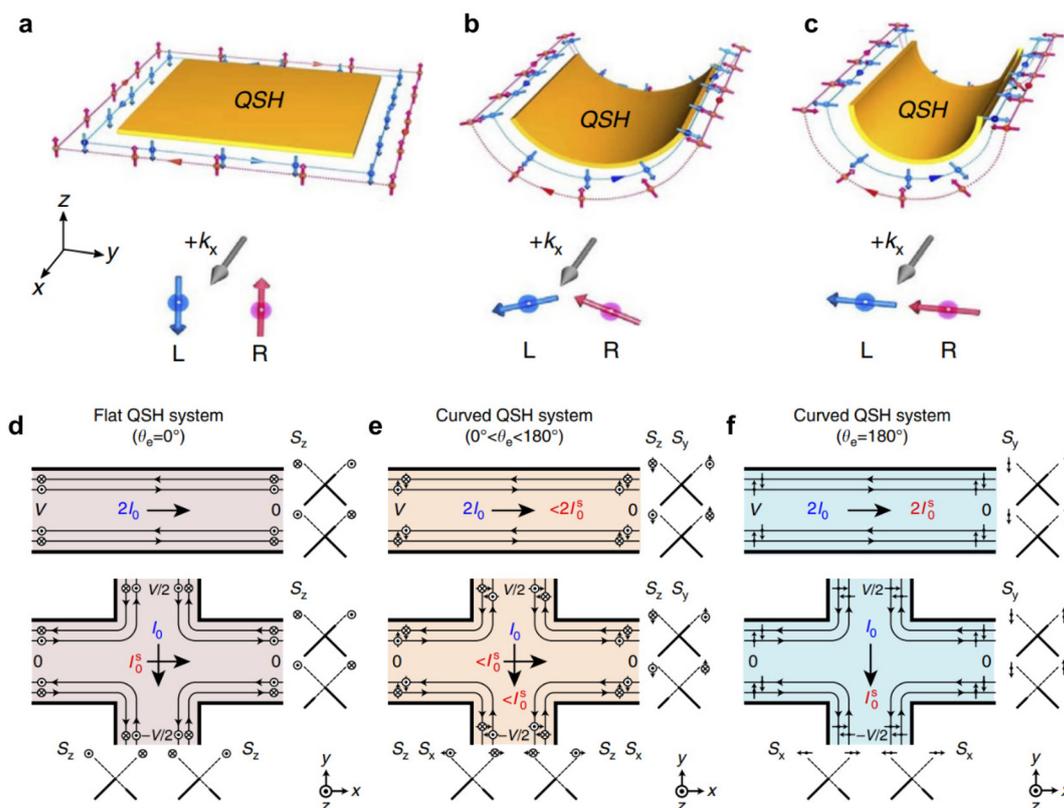

We note that in the field of topological spintronic devices, several main challenges remain to be addressed. First, material selection is crucial, requiring the identification of materials with desired properties such as large topological energy gap, long spin coherence time, and efficient spin manipulation. Secondly, precise control and manipulation of spins in topological devices are essential. This involves utilizing the unique electronic structure of topological materials and employing external perturbations such as electric field, magnetic field, mechanical strain, and optical control. Thirdly, reliable fabrication techniques are needed to create device structures and interfaces while preserving the spin-related properties of the materials. Scalable and low-cost production methods for large-scale topological materials are being explored. Finally, scaling up the fabrication of topological spintronic devices and integrating them into practical systems present significant challenges in terms of scalability, compatibility with existing technologies, and device integration. To address these challenges, extensive research has been conducted on various concepts and proposals for topological devices, and further studies on topological spintronic devices are ongoing.

This section is structured as follows. We begin with introducing the basic concept for generating pure spin current using

2D TI and the nanomechanical architecture for spin rectifying devices application. Then we discuss the efficient control and manipulation of spin degrees of freedom in magnetic TI structures. Next, we briefly review the unique spin structure in topological dislocations. Finally, we discuss the unidirectional spin textures and spin coherent properties in nonsymmorphic materials for novel multi-functional spin transistors.

### 2.1 Perfect spin filtering in curved 2D TI

Quantum spin Hall (QSH) system, two-dimensional (2D) TI, can exhibit exotic spin transport phenomena, mediated by its topologically protected edge channels.<sup>5,6,12,13,55,59</sup> It has the advantage of being able to implement efficient generation and detection of pure spin current, which is one of the key challenges of spintronics. Especially, a transverse edge pure spin current can be generated under a four-terminal device setting.<sup>5,55</sup> For a conventional flat QSH insulator, there are two basic properties, time-reversal symmetry (TRS) and spin conservation, which are of special interest. TRS renders the edge states of a QSH insulator topologically protected to transport robust spin current without elastic back-scattering from non-magnetic impurities. However, spin conservation mandates that there is no net spin current under a two-terminal device setting in a QSH system. Therefore, discovering new mechanism to control the spin current and/or transverse pure spin current in a QSH system is of great importance for spintronics devices. The original proposal to exploit the pure spin current in the QSH system has been demonstrated *via* bending strain engineering.<sup>60–63</sup> In layered materials, curvature or local strains are believed to affect the transport, magnetic, and spin relaxation properties.<sup>64–67</sup> Because the helicity of edge states should not be changed by the deformation, the rotation of orbitals by the bending strain leads to spin rotation.<sup>61</sup> Fig. 2 shows schematics of the adiabatic manipulation of counter-propagating spins along the edge of a curved QSH layer. For the flat QSH layer ( $\theta_e = 0^\circ$ ), there exist both clockwise and counterclockwise edge channels, whose direction was determined by the spin orientation (either up or down) of the occupying electrons. For the curved QSH system ( $\theta_e > 0^\circ$ ), curvature does not remove TRS, and spin/charge currents with opposite polarity still propagates in opposite directions along the edges, which is also reflected by the unchanged edge band structures. However, bending changes the directions of orbital angular momenta, which in turn changes the spin directions subject to the spin-momentum locking property. Spins are no longer conserved along the edges, which is expected to modify non-equilibrium spin transport properties in curved QSH systems under a bias. Specifically, edge spin rotation is achieved by creating spin  $y$  ( $S_y$ ) component in addition to  $S_z$ . At two opposite edges of a QSH ribbon, the  $S_z$  components are antiparallel (pointing in the opposite directions at opposite edges) but the  $S_y$  components are parallel (point in the same directions at opposite edges) to each other along the same direction of charge current. Consequently, a conventional (flat) QSH system conducts only charge current but not spin current under a two-terminal device setting because only  $S_z$  com-

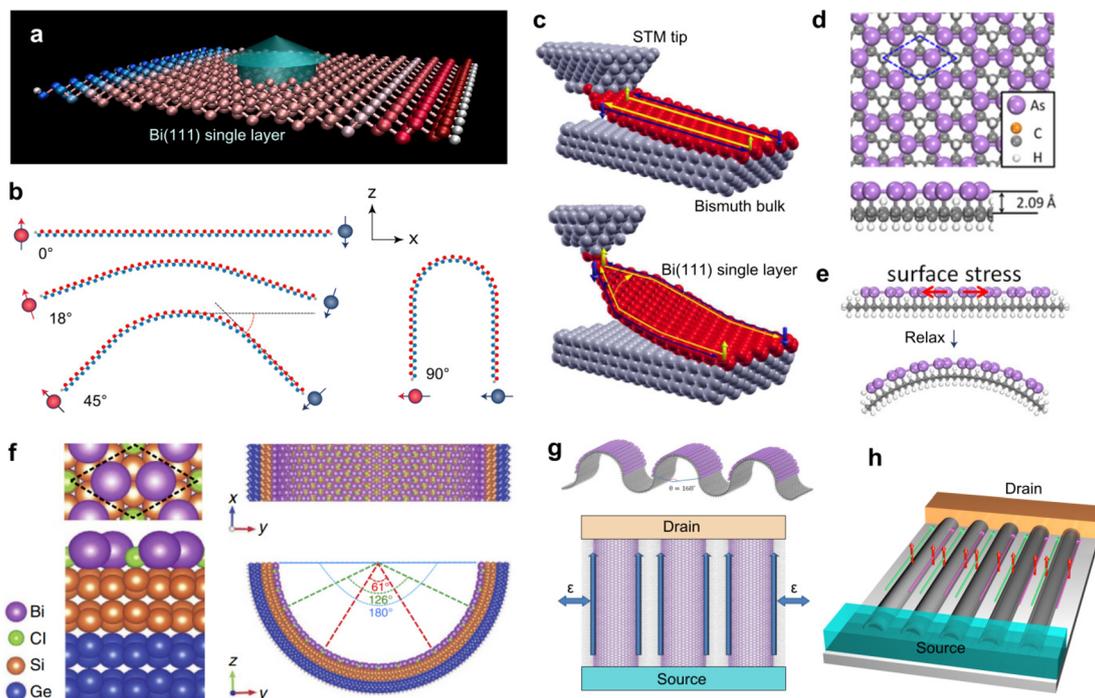

**Fig. 2** (a)–(c) Schematic diagrams of spin current and charge current flowing along the edges as the bending angle  $\theta_e$  increases from  $0^\circ$  to  $180^\circ$ . A pair of edge states counter propagate along all four edges subject to TRS. The spins rotate adiabatically along the curved edges. (d)–(f) Comparison of two-terminal and four-terminal measurement geometries for a flat QSH system ( $\theta_e = 0^\circ$ ), curved QSH system ( $0^\circ < \theta_e < 180^\circ$ ), and curved QSH system ( $\theta_e = 180^\circ$ ), respectively. The arrows indicate the charge current ( $I$ ) (blue sign) and spin current ( $I^s$ ) (red sign) and their flow directions. The unit of  $I$  and  $I^s$  are  $I_0 = \left(\frac{e^2}{h}\right)V$  and  $I_0^s = \left(\frac{e}{4\pi}\right)V$ , respectively. The diagrams to the right and bottom indicate population of the edge states. Reprinted with permission from ref. 61, Copyright 2017 Nature Publishing Group.

ponent exists, while a curved QSH insulator can conduct both charge current and spin current arising from the emergence of  $S_y$  component.

Based on the same physical mechanism, curvature can also modify the transverse pure spin current of QSH systems. More generally, using the Landauer–Buttiker framework,<sup>68</sup> a comparison can be made between the charge and spin transport properties of curved QSH devices and those of conventional (flat) QSH devices in both two- and four-terminal device settings. In a two-terminal geometry [Fig. 2(d)–(f), upper panel], we expect a ballistic two terminal charge conductance ( $I$ ) with conductance unit  $I_0 = \left(\frac{e^2}{h}\right)V$  for all three cases. While the spin current ( $I^s$ ) for the curved QSH device is significantly different from the flat QSH device that conducts only charge current. The spin current varies from 0 to  $\left(\frac{e}{2\pi}\right)V$  according to the bending angle. A curved QSH device can effectively work as a topological half-metal for spin injection, that is, it transports topologically protected completely spin-polarized charge current, and the density of spin current can be tuned by the

curvature. With four terminals setup, the flat QSH device conducts a longitudinal charge current ( $I_l$ ) and a transverse pure spin current ( $I_t^s$ ) [Fig. 2(d), lower panel], while the curved QSH device with  $0 < \theta_e < 180^\circ$  [Fig. 2(e), lower panel] conducts both longitudinal charge current ( $I_l = I_0$ ) and spin current ( $I_t^s < I_0^s$ ) (contributed by  $S_y$  component), as well as a transverse pure spin current  $I_t^s < I_0^s$  (contributed by  $S_z$  component). Interestingly,  $I_t^s(I_t^s)$  continues to decrease (increase) with increasing  $\theta_e$  subject to the conservation of total spin,  $S = S_y + S_z$ , and finally  $I_t^s$  vanishes at  $\theta_e = 180^\circ$  [Fig. 2(f), lower panel].

A practical approach to realize curved QSH systems is nanomechanical architecture of strained nanofilms, which has been proven a powerful method to fabricate nanomembranes, nanotubes, partial or half nanotubes, and nanocoils.<sup>69–71</sup> The general process of nanomechanical architecture proceeds with growth of strained nanofilms on a sacrificial substrate followed by patterning and release (through removal of the sacrificial substrate) of the nanofilms, which will roll-up into different tubular shapes as pre-designed by strain engineering. As a realizable curved QSH system, one promising example is a Bi(111)

**Fig. 3** (a) 2D topological Bi(111) single layer nanoribbon. (b) Cross-sectional view of curved Bi single layer nanoribbon. (h) A proposed spin injector device concept: mass production of self-rolled up QSH nanofilms on a substrate produced by the concept of nanomechanical architecture process, connected with electrodes.

single layer with a puckered honeycomb lattice [Fig. 3(a)]. The Bi(111) single layer has been predicted and confirmed a QSH insulator with a large bulk gap and odd number of helical edge states.<sup>72–76</sup> The concept of spin control through the bending strain can be applied to the Bi(111) single layer.<sup>60</sup> Fig. 3(b) shows schematics of deformation of zigzag Bi(111) nanoribbons and subsequent spin orientation in the edge states. The helical Dirac cone of edge states persists even when the nanoribbon is bent. The orbital rotation by the bending strain leads to the spin rotation to preserve the helicity. When both edges are bent parallel, both edges have the same spin direction, providing channels for spin-polarized currents. In order to achieve mechanical deformation in Bi(111) single layer, one can consider a contact-induced exfoliation of Bi(111) single layer [Fig. 3(c)]. Because the interlayer coupling is about 10 times weaker than the intralayer covalent bonding, once a gentle contact is made on the appropriate surface orientation, retracing the tip can peel off a single layer and bend it in the desired direction.<sup>77</sup>

In addition to Bi(111) single layer, there are other curved QSH systems with self-bending,<sup>78</sup> such as As-graphane<sup>62</sup> and Bi/Cl/SiGe(111) surface.<sup>61</sup> The As-graphane with As deposition on graphene with honeycomb H vacancies has been predicted

as a new QSH insulator with a nontrivial gap  $\sim 83$  meV [Fig. 3(d)]. Because of a large tensile surface stress in the As-graphane system (about  $0.32 \text{ eV } \text{Å}^{-2}$ ), As-graphane nanoribbons will self-bend toward the graphane side [Fig. 3(e)]. After full relaxation, the As-graphane nanoribbon bends to the graphane side with a curved angle (the central angle of the curved nanoribbon)  $\sim 72^\circ$ . The naturally curved As-graphane nanoribbons then exhibit unique spin-filtered transport properties, distinctively different from the flat ones. In terms of feasibility, the surface-based QSH system<sup>14,79–82</sup> has an advantage in its curved structure. It has been predicted that a surface based QSH state forms in a hexagonal Bi overlayer deposited in the halogenated Si/Ge(111) surface, that is, Bi/H(Cl)/Si/Ge(111). If one grows an ultrathin Si/Ge(111) film on a sacrificial  $\text{SiO}_2$  substrate before Cl adsorption and Bi deposition, then the resulting Bi/H(Cl)/Si/Ge(111) nanofilm is readily subject to the nanomechanical architectural process,<sup>71</sup> self-rolling into a tubular shape including a partial cylinder type. Fig. 3(f) shows the atomic structure of Bi/Cl/Si/Ge(111) nanofilm and its self-curved nanoribbon structure. The calculated self-bending curvature of Bi/Cl/Si/Ge(111) is  $0.0136 \text{ nm}^{-1}$ , which satisfies the conditions for generating spin-rectified current with a configuration of parallel edges. Furthermore, a

parallel process<sup>83</sup> that can facilitate mass production of identical partial cylindrical QSH arrays [Fig. 3(g) and (h)], which will function ideally as a robust spin injector device with high spin current density. The proposed a concept of bending strain engineering of spin transport in QSH systems, which is generally applicable to all QSH materials and especially suited for flexible atomic 2D QSH layers or surface-based QSH states on or inside a thin film.

## 2.2 Control and manipulation of spin current in the TI/ferromagnet heterostructure

Efficient control and manipulation of spin degrees of freedom without a magnetic field is one of the challenges in developing spintronic devices.<sup>84,85</sup> Taking inspiration from ordinary ferromagnetic heterostructures, proximity coupling has also been used for TI materials to achieve magnetic order, and thus enable the observation of topological phenomena with thermal stability.<sup>57,86–89</sup> The coupling between the topologically protected surface states and the local magnetic moments can provide more interesting physics at the interface. In addition, the proximity coupling can break the time-reversal symmetry (TRS) while maintaining the TI surface free from impurities or lattice defects, overcoming the problem of large Dirac-mass disorder.

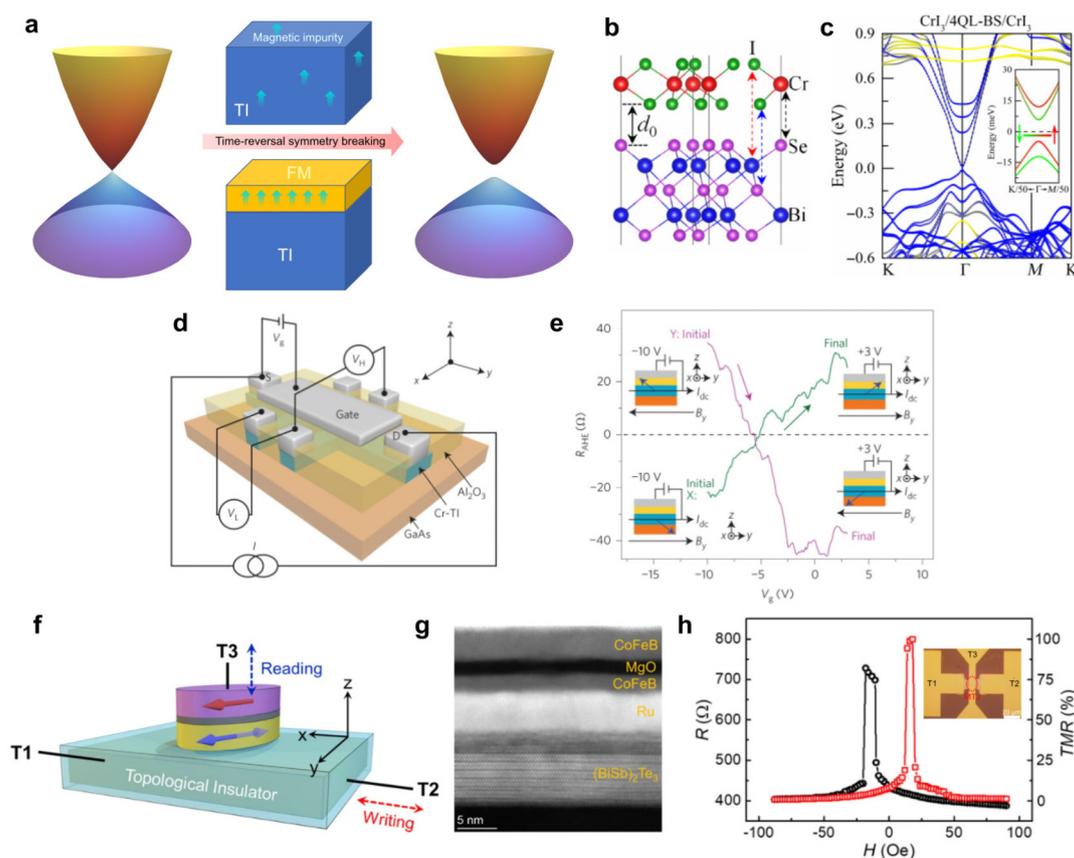

The nontrivial metallic Dirac band on the surface of a 3D TI, which is protected by the bulk topology order is the main characteristic feature. By introducing magnetism to a TI, either by magnetic impurity<sup>90,91</sup> or by proximity coupling to a ferromagnet (FM),<sup>92</sup> TRS can be broken. The breaking of TRS induces a band gap in the Dirac surface states [Fig. 4(a)]. For the design of the next-generation spintronic devices, it is crucial to find efficient ways to magnetize their topological surface states (TSSs) while maintaining their topological features. The magnetized TIs by doping magnetic atoms has been realized in Fe-,<sup>91</sup> Cr-<sup>93</sup> or V-doped<sup>94</sup> (Bi, Sb)<sub>2</sub>Te<sub>3</sub> thin films. There also have been theoretical studies of the effect of magnetic atomic impurities on the topological properties.<sup>95–98</sup> Magnetic impurities in the bulk can lead to a small gap opening at the Dirac point. It was shown that magnetic Fe atoms on the Bi<sub>2</sub>Se<sub>3</sub> surface act as strong Coulomb and magnetic scattering centers, which lead to the creation of odd multiples of Dirac fermions, and that magnetic interaction breaks TRS in the presence of band hybridizations.<sup>91</sup> On the other hand, a promising alternative route to magnetize TSSs is the ferromagnet (FM) and TI heterostructure *via* magnetic proximity effect. This approach provides a spatially uniform magnetization of TSSs and the absence of the dopant-induced scattering. Recently, many theoretical studies have been conducted to find suitable magnetic materials and to understand the physical mechanism occurring at the FM/TI interface.<sup>99–104</sup> Among them, 2D van der Waals ferromagnetic monolayer such as CrI<sub>3</sub> offers an optimal way to magnetize the TSSs [Fig. 4(b)]. The calculated band structure of CrI<sub>3</sub>/Bi<sub>3</sub>Se<sub>3</sub>/CrI<sub>3</sub> shows the gapped Dirac cone of TSSs and lifted spin degeneracies indicating that the TSSs of Bi<sub>2</sub>Se<sub>3</sub> are magnetized by the CrI<sub>3</sub>.<sup>104</sup>

In light of the above two approaches, different magnetic TI structures have been studied to probe the spin-orbit torque

(SOT)-induced magnetization switching. As the first approach, the magnetization switching in the TI/Cr-doped TI heterostructure is reported.<sup>88,105</sup> The Cr-doped TI structure is an ideal platform to study the SOT because it gives very robust ferromagnetism at low temperature.<sup>106</sup> In the TI heterostructure, the Cr-doped TI magnetization can be successfully switched by scanning the longitudinal current and a giant SOT is generated by the current flowing through the heterostructure.<sup>88</sup> Furthermore, the current-induced SOT in Cr-doped TI systems can also be controlled by the gate electric field.<sup>105</sup> Fig. 4(d) shows a top-gated Hall bar structure made of Au(electrode)/Al<sub>2</sub>O<sub>3</sub>/Cr-doped TI/GaAs(substrate). The top gate voltage can effectively tune the carrier density at the Al<sub>2</sub>O<sub>3</sub>/Cr-doped TI interface, and consequently the net SOT in the Cr-doped TI layer can be modulated. The SOT strength modulated by a factor of four by gate tuning within the accessible voltage range, which is 1–2 orders of magnitude larger than that reported in metal/ferromagnet heterostructures.<sup>107–109</sup> Furthermore, it is demonstrated that the magnetization switched by scanning gate voltage with constant current and in-plane magnetic field [Fig. 4(e)]. The gate voltage enabled switching points towards devices applications such as electric field controlled magnetic memories that are compatible with modern field-effect semiconductor technologies. Secondly, SOT-driven magnetization switching also has been demonstrated in FM/TI based structure, where the spin current generated by the strong SOC in TIs exerts a spin torque to the adjacent FM and thus switches the magnetization with a current.<sup>57,110–113</sup> In particular, ref. 113 demonstrated a TI-driven SOT-magnetic random-access memory (NRAM) cell with a state-of-the-art tunneling magnetoresistance (TMR) ratio 102% and an ultralow switching current density at room temperature. Fig. 4(f) show the 3-terminal SOT device of TI-magnetic tunnel junction (MTJ), the writing current is applied between terminal 1 (T1) and T2, where the spin-polarized current in TSSs is employed to provide the SOT and switch the magnetization of the free-layer (B-CoFeB) of the MTJ. For reading, a small vertical current between T1 and T3 is applied to pass through the tunneling barrier MgO, where the tunneling resistance strongly depends on the magnetization orientation between the free-layer (B-CoFeB) and the fixed-layer (T-CoFeB): low resistance for the parallel state (“0” state) and high resistance for the antiparallel state (“1” state), respectively, *i.e.*, the TMR effect. From the cross-sectional scanning transmission electron microscopy results, we see the layer-by-layer (*i.e.*, van der Waals) structure of the TI [(BiSb)<sub>2</sub>Te<sub>3</sub>] and the clear interface between TI and MTJ [Fig. 4(g)]. Fig. 4(h) shows the tunneling resistance *R* and the TMR ratio as a function of the magnetic field *H* at room temperature, where a TMR ratio of 102% indicates the energy consumption is significantly reduced.

## 2.3 Topological dislocation induced unique spin texture with high spin coherency

The structural, mechanical, and electronic properties of dislocations have been intensively studied for decades.<sup>114–116</sup>

They fall into three categories, *i.e.*, edge, mixed, and screw type.<sup>114</sup> In general, dislocations are considered to have a negative impact on materials properties and functionalities. For example, formation of dislocation is the leading mechanism for growth instability of coherent thin films. Dislocations may create scattering centers<sup>115,116</sup> to lower carrier mobility, cause current leakage and act as in-gap deep-level carrier recombination centers.<sup>117,118</sup> Therefore, much research effort in the past has been devoted to alleviating dislocations in semiconductors.<sup>119</sup> However, using the unique structure of dislocation (topological singularities and line defects) and the SOC effect, the ordinarily harmful dislocation turns into a beneficial unit for spintronic devices.<sup>120–124</sup> In a crystalline solid, the motion of an electron is inevitably coupled with its spin orientation through the SOC effect. Hence, discovering new forms of the SOC effect and topological behavior in the dis-

locations that provide more effective means to manipulate spin transport properties is not only of fundamental interest but also critical to the development of spintronic devices.

The extrinsic SOC effect in a crystal requires breaking of inversion symmetry, which commonly occurs on surfaces or interfaces as manifested by the 2D Rashba<sup>125</sup> and Dresselhaus SOC<sup>126</sup> (RD-SOC) effects [Fig. 5(a)]. For the pure Rashba SOC, the spin is always orthogonal to the  $\mathbf{k}$  vector. For the Dresselhaus SOC, the spin can be either parallel or orthogonal to the  $\mathbf{k}$  vector. In the case of equal contribution of Rashba and Dresselhaus effect, the spin-orbit field becomes unidirectional, *i.e.*, the persistent spin texture.<sup>127,128</sup> On the other hand, the SOC in a screw dislocation (SD) is 1D in nature and exists in bulk materials, so it goes much beyond the conventional 2D RD-SOC effect. In ref. 123, it demonstrated the key features of the coherent 1D SD-SOC effect and its main differ-

**Fig. 5** (a) The orientations of the effective electrical field (light gray shaded circle) and spins (red and blue arrows) for the conventional Rashba SOC effect at surfaces or interfaces, for the linear Dresselhaus effect in an asymmetry QW or a strained zinc blende film and combined effect of Rashba and Dresselhaus effect, respectively. ence from a conventional 2D RD-SOC effect [Fig. 5(b)]. For the newly discovered 1D SD-SOC [Fig. 5(b)], spins only rotate in one quadrant with an angle changing from 0 to  $\pi/2$ . Consequently, the 1D SD-SOC will exhibit a significant higher degree of spin coherency because the spins are constrained to vary within a much narrower range of angles. Furthermore, similar to the persistent spin texture in 2D system, an ideal spin texture can be achieved in 1D SD-SOC, albeit be available intrinsically in a single material.

This new type of SOC was confirmed on three representative semiconductors: Ge, GaAs, and SiC.<sup>123</sup> For each material, a model for the single dislocation defect was constructed [Fig. 5(c)]. The crystal field around the defect can be broken into two components—one Rashba-like, the other Dresselhaus-like. In addition, the ratio of these two components depends on the compound's ionicity, which is a measure of how ionic the atomic bonds are. Purely Dresselhaus-like SOC occurs in the compound with the weakest ionicity, Ge, while the Rashba-like contribution dominates in the compound with the strongest ionicity, GaAs. Interestingly, the two contributions are equal in SiC, whose ionicity is between that of Ge and GaAs. The Rashba and Dresselhaus contributions rotate spins in opposite directions, so having an equal contribution of the two produces spins with a fixed orientation [Fig. 5(d)]. Thus, the SD in those compound semiconductors with medium ionicity, like SiC, may be used effectively for suppressing spin relaxation in spintronics devices.

The 1D SD-SOC character in 3D bulk materials can be extended to 1D line defects of 2D systems.<sup>124</sup> 2D materials with atomic thickness and high exposure of surface atoms allow for easy regulation of properties by means of defect engineering.<sup>129</sup> Especially, monolayer transition metal dichalcogenides MX<sub>2</sub> (M = Mo, W; and X = S, Se) suitable for three

critical reasons: (1) controllable defects engineering, (2) a moderate band gap ( $\sim 1\text{--}2$  eV) providing the possibility to create ideal SOC states free of interference from bulk states, (3) large SOC strength enabling effective manipulation of spin states. In ref. 124, the proposed chalcogen vacancy line defects are oriented along the armchair direction of MX<sub>2</sub>, and the two parallel aligned line defects are separated by a single atomic line, as shown in Fig. 5(e). The spin-projected conduction bands of the double line defects engineered WS<sub>2</sub> where are expectation value of spin  $x$  component is clearly shown in Fig. 5(f). These in-gap defect states are completely isolated from other bulk bands. Spin components of  $S_y$  and  $S_z$  are both zero, and the only nonzero spin component is  $S_x$  along the entire path of  $\Gamma$ -X. This suggests that the defect states have uniaxial spin polarizations oriented along the  $x$  direction, which forms exactly the desired unidirectional SO field. Interestingly, when the relative positions of double line defects change, spin polarization of the defects states changes from  $x$  to  $y$  direction. The emerging unidirectional SO field is subject to both the structural symmetry and 1D nature of the line defects. The orientation of the SO field can be effectively tuned by altering the line defect spatial distribution.

#### 2.4 Persistent spin texture in 2D non-centrosymmetric materials

Rich and exotic electronic properties may arise through symmetry breaking in 2D materials, which have recently attracted much attention for both fundamental interest and novel spintronic device concepts. The SOC in inversion asymmetric system has been an important factor in spintronics since the development of the Datta–Das spin field-effect transistor,<sup>130,131</sup> which induces the coherent spin precession governed by the Rashba SOC [Fig. 6(a)]. However, the Rashba SOC is rarely compatible with long spin lifetimes because it breaks the spin

**Fig. 6** (a) and (b) The conventional Rashba and PST spin configurations appear under the out-of-plane ( $z$ -direction) and in-plane ( $x$ -direction) electric field, respectively. (c) The unidirectional spin-split Fermi surface with the long-lived persistent spin helix mode. The spheres (arrows) represent electrons (spin directions).  $l_{\text{PSH}}$  denotes the persistent spin helix wavelength. rotational symmetry and suffers from fast spin decoherence in a diffusive transport regime.<sup>128</sup> Thus, acquiring effective electrical spin manipulation while preserving the long spin lifetime has been elusive. As an exceptional example, in the case of PST [Fig. 6(b)], the spin-orbit field is unidirectional which results in a spatially periodic mode known as a persistent spin helix (PSH)<sup>132</sup> [Fig. 6(c)]. In addition, recent studies reported that the PSH feature is closely related to the topological characters, such as Berry curvature dipole, valleytronics, and non-linear Hall effects.<sup>133,134</sup> The PSH has spatial periodicity with the wave length  $l_{\text{PSH}}$  defined as the distance over which the spin direction repeats. The combined spin-orbit field is aligned in a uniaxial direction with SU(2) symmetry, which is robust against spin-independent scattering and renders the spin lifetime ultimately infinite<sup>128</sup> [Fig. 6(d)]. It has been demonstrated that the PSH states can be achieved in specific noncentrosymmetric bulk materials where the PSH state is enforced by the nonsymmorphic space group symmetry of the crystal.<sup>135,136</sup> However, these states survive only along certain high-symmetry paths in the Brillouin zone and are likely over-

whelmed by other non-PSH states in the same energy window, which severely hamper their practical applications. Therefore, it is highly desirable to explore material platforms for realizing the PSH states.

The ideal target system for PSH states should simply possess a unidirectional, field-tunable, and large SOC. Specifically, atomically thin SnTe film, recently synthesized using molecular beam epitaxy, is the most promising material potentially capable of satisfying the criteria.<sup>137–139</sup> Fig. 6(e) shows the SnTe monolayer structure. The ions are arranged in two buckled layers with distortions inducing the spontaneous polarization along  $x$ , while the tiny anisotropy between the lattice constants  $a$  and  $b$  emerges as a natural signature of the ferroelectric phase. When the ferroelectric polarization is aligned along the  $x$ -axis, the electronic structure of the SnTe monolayer exhibits two valleys near points X and Y<sup>139</sup> [Fig. 6(f)]. In particular, the energy levels without the SOC are fourfold degenerate, while the SOC splits them into doublets over the entire Brillouin zone (BZ) except for the  $\Gamma$ -X line. Furthermore, these doublets split into singlets with eigen-

values of spin operator  $S_z$ , indicating the PST (anti-)aligned in the out-of plane direction. The spin texture of topmost valence band clearly shows unidirectional PST aligned along the  $z$ -direction. The estimated  $l_{\text{PSH}}$  of SnTe monolayer falls within the range 8.8–18.3 nm which improves the suitability for use in nano-size spin transistors by handling the rapid but coherent spin precession.<sup>138</sup> Another promising material platform is a buckled Bi(110) monolayer.<sup>133,134</sup> A notable structural feature of Bi(110) monolayer is the finite out-of-plane buckling, resulting from the vertical shift of the two centered Bi atoms [Fig. 6(g)]. The structural distortion creates internal in-plane ferroelectricity with inversion asymmetry. Similar to SnTe monolayer, the in-plane ferroelectricity induces a momentum-independent spin orientation. As shown in Fig. 6(h), a unidirectional spin splitting is observed along the  $k_y$ -direction. The glide mirror symmetry allows the  $z$  spin component only in each spin-polarized band. Ref. 134 further shows that such novel electronic properties can be secured in a Bi(110) film grown on a proper substrate such as a Bi(110)/NbSe<sub>2</sub> heterostructure [Fig. 6(i)]. Furthermore, Bi(110)/NbSe<sub>2</sub> heterostructure provides a promising platform for realizing a sizable Berry curvature dipole and nonlinear Hall effect which fundamentally related with PST.

Considering the non-volatile control over the ferroelectricity, SnTe and Bi(110) thin films could enable novel multi-functional spin transistors.<sup>138</sup> As a simple sketch for a device application, a spin-valve-like experimental setup composed of ferromagnetic electrodes and a noncentrosymmetric thin film as a transport channel could facilitate two switching modes by employing a ferroelectric-coupled PSH. Ferromagnetic metal leads at both ends have in-plane and orthogonal spin orientations, and the ferroelectric polarization in the monolayer channel aligns perpendicular to the transport direction. Due to the orthogonal spin configurations between the ferromagnetic source and drain electrodes, the electron spin at the end of the monolayer channel is either parallel or antiparallel to the spin orientation of the drain, leading to an on- or off-state, respectively. The on-off switching could be controlled by flipping either the electric polarization of the monolayer channel [Fig. 6(j)] or the magnetic polarization of the ferromagnetic electrodes [Fig. 6(k)]. Combined with the charge switching mechanism along the polarization direction, we can design the multi-functional cross-shaped charge-spin transistor sketched in Fig. 6(l).

### 3. Topological electronic devices

Considering the most prominent property of topological materials,<sup>140</sup> *i.e.*, TSSs with spin-momentum locking, they are touted as promising electronic transport materials with potentially higher transport efficiency and lower power consumption. In this section, we will review recent studies on the application of topological materials in electronic devices. We start from the usage of TIs in traditional field-effect transistor (FET), which are termed as topological FET (TFET), and briefly

review proposals of using different categories of topological materials for TFET based on topological phase transitions. Then, the application of topological materials in another fundamental electronic device building block, p-n junction, in both in-plane and vertical configurations are reviewed. Furthermore, some less mentioned applications of topological materials in electronic devices will be briefly outlined.

#### 3.1 Topological field-effect transistor

Field-effect transistors have built the foundation for modern electronic devices that were believed to continually follow Moore's Law to achieve faster and more powerful digital information processing ability. One key contribution to such amazing achievement is the continued miniaturization of device components, such as complementary metal-oxide-semiconductor (CMOS) unit, which, however, may have eventually reached its limit that prevent from further development. To meet the further future demand on performance improvement, one alternative pathway for advancement is to decrease the power consumption and find novel materials that are less affected by the confinement effect. There are several promising attempts in term of architecture revolution, such as vertical transport FET,<sup>141</sup> gate-all-around transistors,<sup>142</sup> and crossbar-based computing architectures,<sup>143</sup> *etc.* These advancements have gradually matured and been adopted in the next generation of electronic devices.<sup>141</sup> On the other hand, extensive research efforts have been made in discovering new materials to replace the conventional semiconductors, which would lead to a more disruptive technology advancement. Several most studied families of materials include but not limited to organic semiconductors,<sup>144–146</sup> ferroelectric semiconductors,<sup>147–149</sup> two-dimensional materials,<sup>150–152</sup> and topological materials,<sup>153–155</sup> which however all have their pros and cons. There are already several comprehensive reviews available about some of these novel functional materials for applications in FET,<sup>156–158</sup> here we will focus on the emerging topological materials studied in TFET.

As mentioned above, a number of different categories of topological materials have been proposed theoretically and discovered experimentally, including insulating, metallic and semi-metallic materials of different dimensionality.<sup>7,9,15,16,55,159–166</sup> Among them, TIs that have bulk insulating states and spin-momentum locked edge/surface states are considered as the most promising candidates in TFET at the early stage of the study.<sup>7,140,159,160</sup> This is mainly because it is believed that the bulk insulating state can adopt conventional on-off switching mechanism, and the additional TSS without backscattering and thus no energy dissipation may facilitate more efficient charge transport and lower power consumption.

One well-studied case is based on 3D TIs, *e.g.*, Bi<sub>2</sub>Se<sub>3</sub> and other binary sesquichalcogenides,<sup>16,167–169</sup> which are directly employed as a channel material in FET.<sup>170–174</sup> There are several key challenges that have been encountered and yet to be fully resolved, *e.g.*, (i) feasible tuning of carrier density of TIs through electric field; (ii) relatively high bulk conductivity

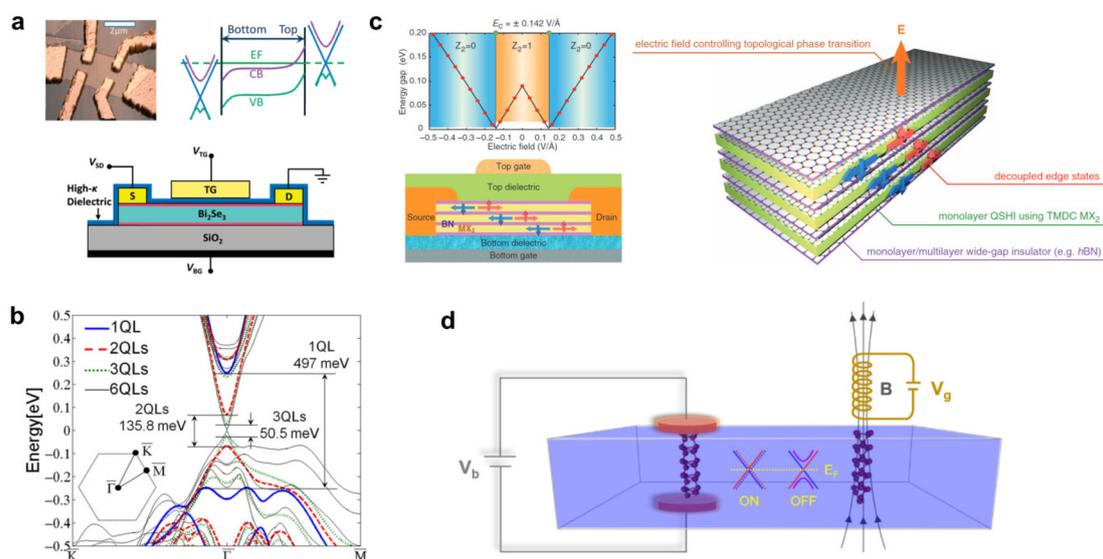

compared to the TSS; (iii) high bulk carrier concentration caused switching difficulty between n- and p-type carriers; (iv) constrained operation temperature limited by relatively small band gaps of known TIs, *etc.*

Several potential solutions have been proposed and tested experimentally.<sup>170–174</sup> One of the initial studies based on Bi<sub>2</sub>Se<sub>3</sub> thin film applied a dual gate configuration to achieve an independent-tuning of carrier density through either top or back gate, as shown in Fig. 7(a).<sup>170</sup> Parallel bulk and surface state contributions to the total conductance were observed and an ambipolar conduction was demonstrated. To reduce the contribution of trivial bulk electrons to the conductivity, thin films were proposed for TFET devices to take advantage of the confinement effect.<sup>175</sup> With the decreasing film thickness, the bulk state moves away from the Fermi level, leading to substantially reduced bulk conductivity, as shown in Fig. 7(b).<sup>176</sup> Bi<sub>2</sub>Se<sub>3</sub> thin film with different thickness (3–14 nm) was studied, which showed successful electron depletion for both surface and bulk state through gate voltage control in TFET. Also an insulating state was observed when the thickness is reduced below 3.5 nm.<sup>175</sup> However, such insulating state is presumed to be caused by the coupling of the top and bottom surface state that destroys the topological feature and forms a conventional trivial insulator.<sup>177–179</sup>

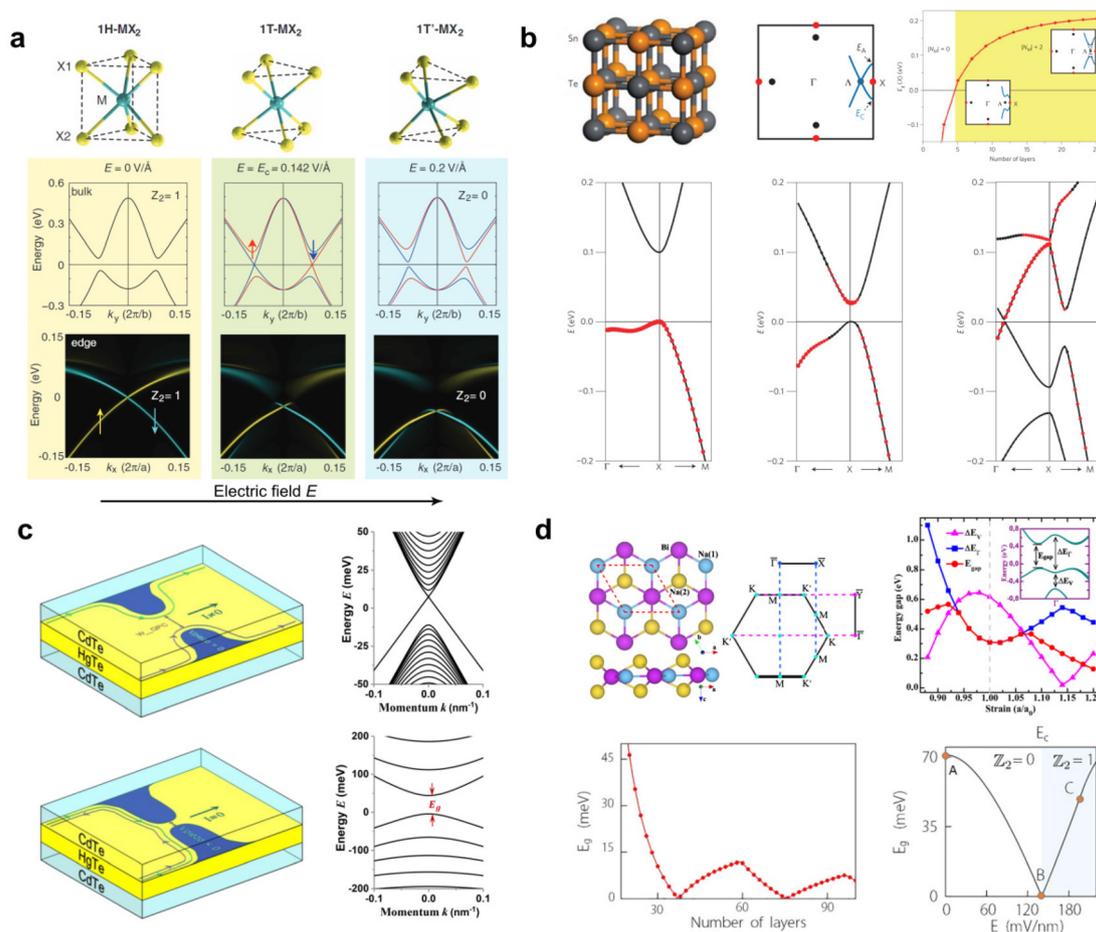

Another difficulty related to tuning the carrier type, which cannot be fully resolved by reducing the film thickness, is the residual charge carriers contributed by crystal defects or environmental doping. Suitable element doping is proposed to shift the Fermi level to conduction band edge and thus reduce the bulk carrier concentration, in order to realize successful

switching between n- and p-type carriers through gate voltage control. Two feasible approaches had been successfully demonstrated experimentally, through either Ca doping<sup>173</sup> or forming ternary TIs (Bi<sub>x</sub>Sb<sub>1-x</sub>)Te<sub>3</sub> by composition tuning.<sup>174</sup> In general, many efforts have been made for the application of TFET, which however are constrained by the gap size of Bi<sub>2</sub>Se<sub>3</sub>, even though the gap size could increase through confinement effect. In addition, all the transport data show either parallel contribution from bulk and surface states of a TI or a completely insulating state induced by further decreasing the film thickness that destroys the TSS.

To solve the aforementioned issues, another proposal that relies on the electric-field-induced topological phase transition between normal insulator (NI) and TI has been brought up to serve as the foundation for the TFET, as shown in Fig. 7(c).<sup>180,181</sup> Specifically, the device is built using 2D van der Waal topological materials, *e.g.*, transition metal dichalcogenides (TMD), which show tunable topological states through either vertical electric field and/or strain, shown in Fig. 8(a).<sup>180</sup> A series of large-gap 2D TMD TI candidates have been studied theoretically, and a novel TFET was proposed by stacking TMD TIs with wide-gap NIs, as shown in Fig. 7(c). Several advantages have been discussed, including easy switch between NI and TI, *i.e.*, OFF and ON states; better control of the band gap through external electric field; multiple conduction channels through decoupled multiple-layer set up in the heterostructure; easier thickness control of the 2D materials to minimize devices size.<sup>180</sup> Instead of using the TI/NI state as the ON/OFF state, recently, a TFET based on tunable topological dislocation states with quantized conductance for both ON

and OFF states was proposed,<sup>182</sup> as shown in Fig. 7(d). In the proof-of-concept device, two topological screw dislocation states in three-dimensional TIs can be controlled separately by two local fields, which support two quantized conducting states ( $2e^2/h$  and  $e^2/h$ ) that effectively serve as ON and OFF states, respectively. As both ON and OFF states are topologically protected with quantized conductance, the TFET is rather robust, precise, and energy efficient, which may serve as a new framework for realizing high-fidelity topological quantum devices.

Similarly, several different mechanisms for inducing topological phase transitions have been proposed for various topological materials. For example, topological phase transition in a family of topological crystalline insulators, such as the one by applying an electric field perpendicular to the SnTe film, has been studied, as shown in Fig. 8(b), and a high on/off operation speed is expected.<sup>183</sup> Fig. 8(c) shows strain modulation of topological states in a piezotronics transistors based

on topological heterostructure HgTe/CdTe.<sup>184</sup> Also, one experiment demonstrated another interesting topological phase transition between topological semimetal, TI and trivial insulator in Na<sub>3</sub>Bi system.<sup>185</sup> The bulk topological semimetal phase of Na<sub>3</sub>Bi naturally transforms into a TI in a thin film of a few layers thick owing to confinement effect, which can be further tuned into a trivial NI through electric field, as summarized in Fig. 8(d).<sup>185–187</sup>

To compare the performance between the newly proposed TFET and other theoretically proposed and experimentally well-developed FET technologies, two factors, *i.e.*, switching delay and its associated switching energy, were studied for benchmarking.<sup>152,181</sup> The results of comparison suggest that TFET may be able to compete with current high-performance CMOS technologies for its potentially low power consumption with similar switching speed. However, the application of TFETs remains challenging due to their generally large capacitance, and the early expectation of high mobility due to TSS

remains elusive.<sup>152</sup> Better electric field control with suitable selection of topological materials is necessary to achieve new breakthrough that could potentially disrupt the current information processing technology.

### 3.2 Topological p–n junctions

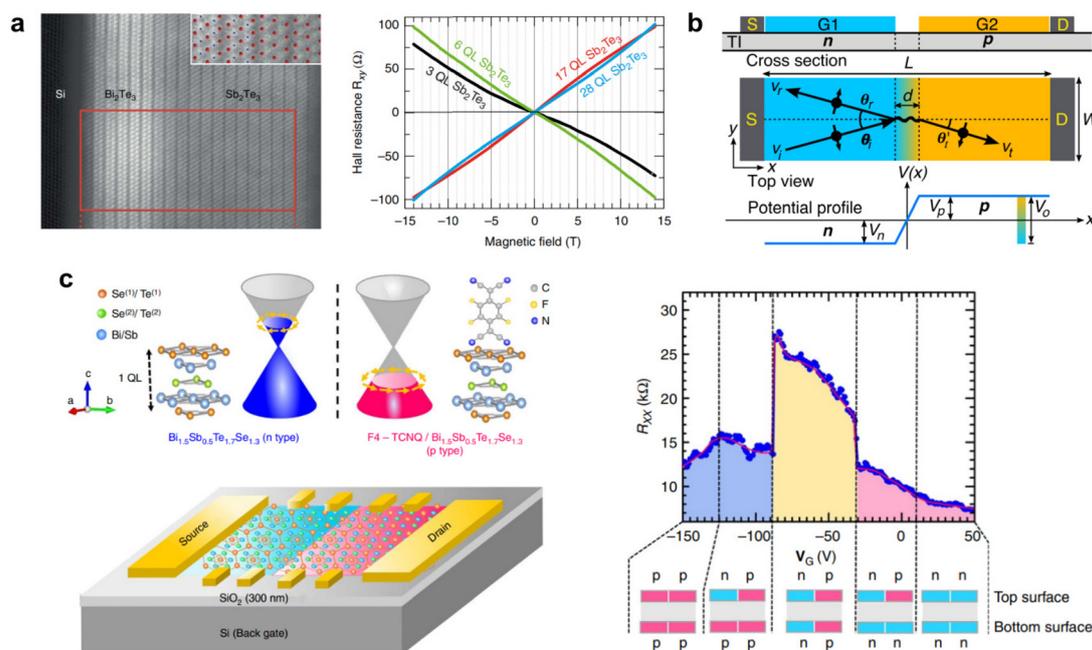

Another fundamental building block of modern electronic devices is p–n junction, which consists of an interface between p-type and n-type semiconducting materials. Its unique feature of one-directional current flow makes it the key component for many electronic devices, such as diode, transistors, and integrated circuits. Similar structure can be created by stacking topological materials with electron and hole doping, which however does not serve the same purpose as traditional p–n junctions and possesses quite distinct properties. Unlike conventional p–n junction, where the junction is depleted of charge carriers that is non-conductive. The topological p–n junction is believed to form a standing wave state<sup>188</sup> at the interface due to the interference between the incident and reflected waves, which can further induce a gapless chiral edge state through a perpendicular magnetic field.<sup>189</sup>

Though the application of topological p–n junction in electronic devices was not well justified, it does demonstrate several promising features for useful application in other aspects. For example, such p–n junction has been used to tune the chemical potential of the topological Dirac point.<sup>190</sup> This is realized in a vertical p–n junction with epitaxial  $\text{Sb}_2\text{Te}_3/\text{Bi}_2\text{Te}_3$  heterostructure, as shown in Fig. 9(a), where the chemi-

cal potential is able to shift about 200 meV by simply changing the  $\text{Sb}_2\text{Te}_3$  layer thickness. It provides one feasible pathway to study exotic quantum states related to Dirac points.<sup>190</sup>

Motivated by the graphene p–n junction that shows angle-dependent transmission (chiral tunneling),<sup>191</sup> topological p–n junction is expected to show similar chiral tunneling behavior. Theoretical calculations show that ideal topological p–n junction indeed allows only the transmission of electrons with very small incident angle due to the chiral tunneling effect, as shown in Fig. 9(b).<sup>192</sup> Moreover, those electrons all possess the same spin due to the spin-momentum locking. Such special transmission behavior makes topological p–n junction a promising spin filter that generates pure spin current. Because all the other electrons are reflected, it could also substantially reduce the charge current that helps to reduce power consumption.<sup>192</sup> Also, a very similar spin filtering phenomenon (spin-dependent Mach–Zender interferometer) was proposed for the topological p–n junction around the same time.<sup>193</sup> Differently, an external perpendicular magnetic field is required to tune both the top and bottom surfaces into the quantum Hall regime to function as the spin filter through electronic gate control.<sup>193</sup>

Along with the theoretical demonstration of the aforementioned intriguing phenomena, several proposals have been made experimentally, such as composition graded doping and electrostatic gating.<sup>189</sup> Beside the vertical topological p–n junction formed through epitaxial  $\text{Sb}_2\text{Te}_3/\text{Bi}_2\text{Te}_3$  heterostructure,<sup>190</sup>

**Fig. 9** (a) Vertical topological p–n junction built through epitaxial  $\text{Sb}_2\text{Te}_3/\text{Bi}_2\text{Te}_3$  heterostructure that shows feasible control of chemical potential with different  $\text{Sb}_2\text{Te}_3$  thickness. Reprinted with permission from ref. 190, Copyright 2015 Nature Publishing group. (b) Chiral tunneling of topological p–n junction that forms an ideal spin-filter. Reprinted with permission from ref. 192, Copyright 2015 American Physical Society. (c) Formation of in-plane topological p–n junction through half-film molecular adsorption, that shows feasible electronic gate control. Reprinted with permission from ref. 194, Copyright 2016 Nature Publishing group.

in-plane p–n junction has also been experimentally realized.<sup>194,195</sup> Based on an n-type TI thin film,  $\text{Bi}_{2-x}\text{Sb}_x\text{Te}_{3-y}\text{Se}_y$ , half of the thin film is properly treated by organic acceptor molecules that transform into a p-type TI while the other half is untouched that remains n-type, which forms an in-plane topological p–n junction, as shown in Fig. 9(c). Through proper field control from both top and bottom gates, distinct transport behaviors were observed, confirming characteristic p–n junction features.<sup>194</sup>

### 3.3 Other topological electronic applications

Beside the most fundamental application of topological materials in electronic devices, there are quite a few less known but still important aspects where topological materials could be useful. One is the interconnect of the CMOS devices, where the traditional metallic interconnect is severely limited by the finite size effect due to the fast increase of the resistivity and switching delay with the decreased size.<sup>196</sup> Considering the high mobility and lack of back-scattering feature, TIs could potentially serve as efficient interconnect materials. Theoretical modeling using  $\text{Bi}_2\text{Se}_3$  as interconnect has been performed through real-space transport calculation, which however shows that the mobility becomes much lower than Cu interconnect due to strong acoustic phonon scattering at room temperature.<sup>196</sup> A larger-gap TI with weak acoustic phonon scattering is necessary for such application.

In addition, application of topological materials in Josephson bifurcation amplifier has been proposed to form a topological Josephson junction,<sup>197</sup> which could help to understand the Majorana bound state and superconducting qubit-based quantum information processing technology. The devices based on Dirac and Weyl materials possess distinct characteristics and offer unique advantages in various applications.<sup>9</sup> The Dirac materials, characterized by their linear dispersion relation, exhibit massless quasi particles with high mobility. This property enables efficient charge transport making them promising for high-speed electronic devices and low-power consumption applications. Recently, FET chiral devices<sup>198</sup> are demonstrated with Dirac semimetal  $\text{PtSe}_2$  showing the ON/OFF ratio of more than  $10^3$ . On the other hand, Weyl semimetal exhibits a different type of behavior, with Weyl nodes acting as magnetic monopole-like sources or sinks of Berry flux. This gives rise to unique transport properties, including the chiral anomaly and the Fermi arc surface states. The existence of Weyl fermions opens up possibilities for high-mobility electronics and potential applications in quantum computing. With strong SOC and broken inversion symmetry, exotic spin textures enable a large spin Hall effect that can efficiently convert the charge into spin current in a type-II  $\text{WTe}_2$  Weyl semimetal.<sup>199,200</sup> While both Dirac and Weyl devices share similarities in terms of their topological nature, their distinct band structures and associated phenomena provide different applications. There is also another interesting field that uses non-Hermitian topological systems as novel high-precision sensors.<sup>201</sup> The key design principle is to couple the boundary conditions that define the non-Hermitian

topological systems with those measurable physical quantities. Theoretical modeling finds these novel sensors show increasing sensitivity with the size of the device and high stability against perturbations.<sup>201</sup>

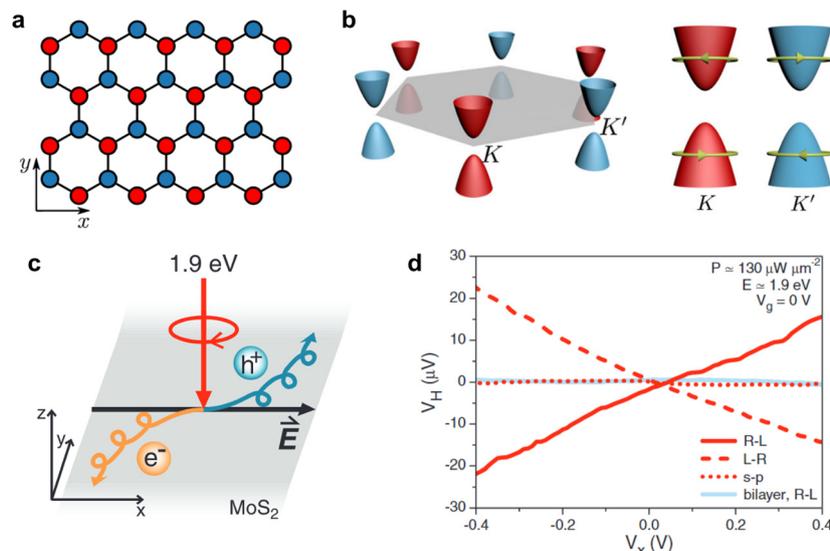

## 4. Topological optoelectronic devices

In this section, we review optoelectronic device applications of topological materials and the inherent topological protection of edge states due to their non-trivial topology. This section is divided into four parts. First, we discuss an important class of topological materials that use valley degree of freedom in applications ranging from quantum computation to optical isolators. Next, we introduce the notion of photonic TIs and their application in optoelectronic devices including TI lasers. Third part deals with the application of TI surface states and topological Dirac states in plasmonic materials and photodetectors. Finally, we discuss about topological FB and its role in optoelectronics focusing on a recent proposal on yin-yang FBs. In recent years, there have been reviews on optoelectronics using TIs which focused on plasmonics,<sup>202–204</sup> photonics,<sup>205–207</sup> and valleytronics.<sup>208–210</sup> We provide an overview of each of these subjects. Readers are encouraged to go through individual reviews and references therein for more elaborate details.

### 4.1 Valleytronics

Valleytronics deals with the design of electronic and optoelectronic devices exploiting the fact that electrons, holes, and excitons behave differently when occupying one valley *versus* the other. Valleys are local energy minima in the conduction band in association with local maxima in the valence band, where excited carriers are energetically degenerate but differ in crystal momenta. One can also assign a valley pseudospin index denoting the localization of particles in a particular valley.<sup>210,211</sup> In contrast to spintronics, where electronic spin can be easily manipulated using external fields, it is generally rather difficult to manipulate particles in a valley due to very weak coupling of valley pseudospin to external fields. In addition, the lifetime of particles occupying the valley needs to be significantly higher in order to make useful valleytronic devices.<sup>208</sup>

Two quantities that can be used to distinguish different valleys and to enable, in principle, valleytronic device applications are – Berry curvature and orbital magnetic moment. In other words, if two valleys have different Berry curvature and orbital magnetic moment, they can be distinguished by using electric and magnetic fields, respectively. Important material examples are graphene,<sup>212</sup> and 2D molybdenum disulfide ( $\text{MoS}_2$ );<sup>213</sup> both possess valleys at high-symmetry reciprocal points K and K' in the Brillouin zone, which are time-reversed images of each other imposed by the underlying hexagonal lattice symmetry.

**Fig. 10** Valley Hall effect in MoS<sub>2</sub>. (a) Schematic of honeycomb lattice with a staggered potential, *i.e.*, sublattices A (red) and B (blue) have different on-site energies, as is the case in MoS<sub>2</sub>. (b) Gapped Dirac cones at valley K and K' with opposite Berry curvature denoted in red and blue respectively. Circularly polarized light of one chirality can excite electrons only in one valley due to opposite effective magnetic field for the two valleys. (c) Upon breaking time reversal symmetry under circularly polarized light, a net valley polarization leads to anomalous Hall effect as carriers in two valleys flow in opposite directions. (d) The source–drain bias ( $V_x$ ) dependence of Hall voltage ( $V_H$ ) of monolayer MoS<sub>2</sub> under R–L modulation (red, solid line), under L–R modulation (red, dashed line), under linear s–p modulation (red, dotted line), and of bilayer MoS<sub>2</sub> under R–L modulation. Linear dependence of  $V_H$  on  $V_x$  for only R–L and L–R modulation indicates photoinduced valley polarization of monolayer MoS<sub>2</sub> which is absent in bilayer MoS<sub>2</sub>. Reprinted with permission from ref. 213, Copyright 2014 Science and from ref. 209, Copyright 2021 Wiley.

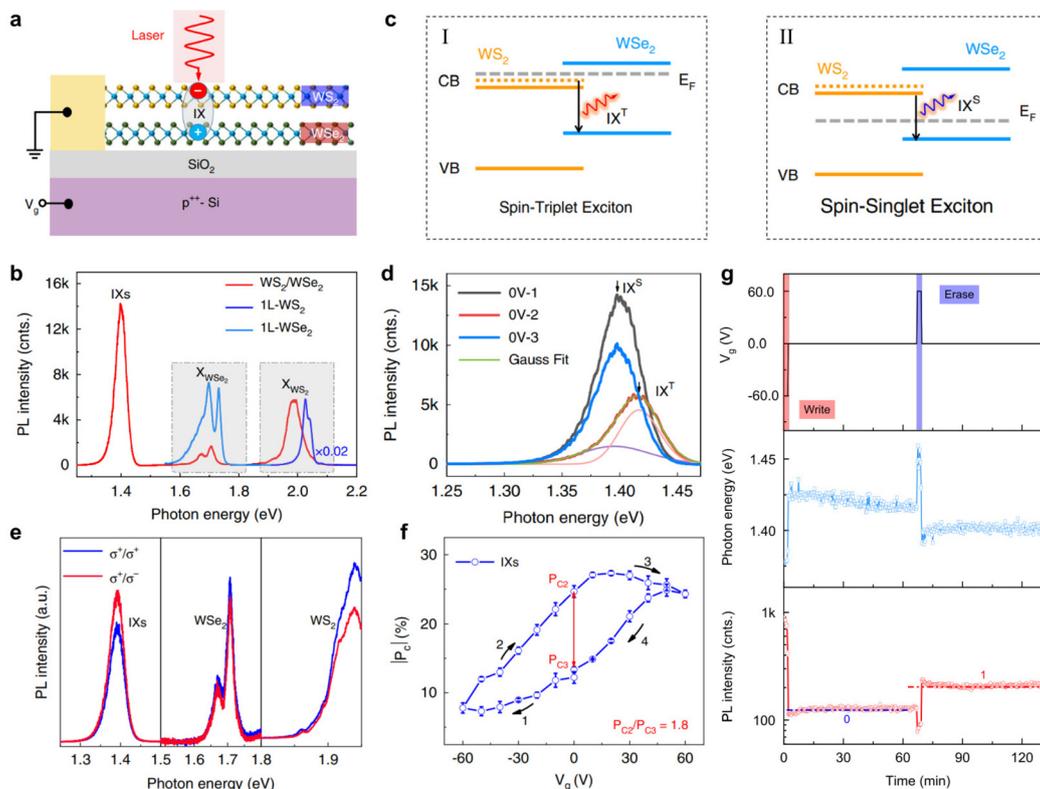

In case of MoS<sub>2</sub> inversion symmetry is broken<sup>212</sup> due to staggered structure of its lattice [Fig. 10(a)] which leads to different Berry curvatures at K and K'. Naturally, a valley Hall effect was observed in MoS<sub>2</sub> in 2014.<sup>213</sup> The two valleys experience opposite effective magnetic field [Fig. 10(b)] which allows for valley polarization under a circularly polarized light and the detection of valley Hall effect, *i.e.*, electrons from different valleys move in opposite direction [Fig. 10(c)]. The experimentally measured dependence of anomalous Hall voltage ( $V_H$ ) on the bias voltage ( $V_x$ ) is shown in Fig. 10(d) for MoS<sub>2</sub> in the presence of circularly polarized light. Under R–L modulation  $V_H$  scales linearly with  $V_x$  which is a signature of photoinduced anomalous Hall effect driven by a net valley polarization. Similarly, it can also be shown that broken inversion symmetry allows for the existence of orbital magnetic moment responsible for optical circular dichroism and valley optical selection rules.<sup>208,214–216</sup>

The unique valleytronic properties of these 2D materials make them attractive for various applications such as, quantum bit for quantum computation,<sup>217–219</sup> quantum key distribution which is an important element of quantum communication relying on generation of polarized photons and remote detection of polarization state,<sup>208</sup> and valleytronic-based optical isolators<sup>208</sup> which make use of inherent optical dichroism of valleytronic materials.<sup>214–216</sup> In addition, the topological currents and optoelectronic properties associated with valley effects can be utilized in the design of transistors and efficient switching devices.<sup>220–222</sup> One such application was recently shown<sup>223</sup> using interlayer excitons in van der

Waals heterostructure of TMDs with a non-volatile memory function, demonstrating a viable route towards valley polarized information processing. Fig. 11(a) shows the schematic of the device consisting of layers of WeS<sub>2</sub> and WS<sub>2</sub> with interlayer excitons (IXs) formed at photon energy of about 1.4 eV [Fig. 11(b)]. Depending on the chemical doping levels the excitons can be in singlet (IX<sup>S</sup> at 1.40 eV) [Fig. 11(c)I] or triplet state (IX<sup>T</sup> at 1.42 eV) [Fig. 11(c)II] with a lower photoluminescence (PL) intensity of IX<sup>T</sup> [Fig. 11(d)]. The valley polarization of excitons can be seen from Fig. 11(e) where the helicity resolved PL data is plotted. IXs show negative circular polarization as evident from a higher cross-polarized ( $\sigma^-/\sigma^-$ ) than the co-polarized ( $\sigma^+/\sigma^+$ ) PL component, which also leads to interesting excitonic hysteresis [Fig. 11(f)] in the degree of valley polarization. These properties of IXs can be used to create valley-addressable memory where the periodic behavior of photon energy of IX emission and PL intensity can be considered analogous to conventional read, write and erase operations while treating the intensity levels of IX<sup>S</sup> and IX<sup>T</sup> at 1.40 eV and 1.42 eV as bits 0 and 1, respectively, with long retention times as shown in Fig. 11(g).

## 4.2 Topological photonics

The seminal work by Haldane and Raghu in 2005<sup>224,225</sup> introduced the notion of topology in electromagnetic waves, leading to the origin of topological photonics. They considered electromagnetic waves in two-dimensional spatially periodic devices embedding time-reversal-breaking magneto-optical elements, so called photonic crystals,<sup>226,227</sup> and illustrated that

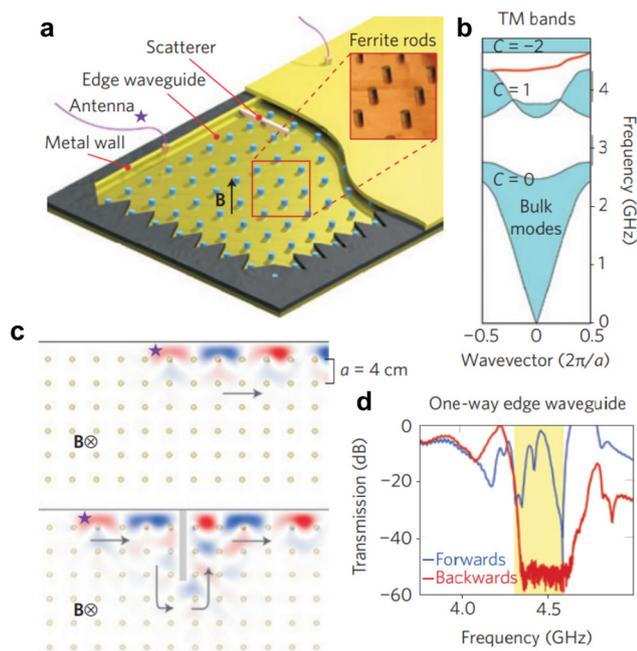

**Fig. 11** Memory device using valleytronic properties of TMDs. (a) Schematic of the device containing van der Waals heterostructure (HS) of WS<sub>2</sub> and WSe<sub>2</sub> over SiO<sub>2</sub>/p<sup>+</sup>-Si substrate. (b) PL spectra of the HS and monolayer WS<sub>2</sub> and WSe<sub>2</sub>. IX represented interlayer exciton. (c) Mechanism for the formation of spin singlet (IX<sup>S</sup>) and triplet (IX<sup>T</sup>) IX excitons. Dotted yellow line represents upper spin-split conduction band. Gray dashed line denotes the Fermi level. (d) PL spectra of IXs with different scanning sequences (e) Helicity resolved PL spectra with cross-polarized (σ<sup>+</sup>/σ<sup>-</sup>) and co-polarized (σ<sup>+</sup>/σ<sup>+</sup>) PL component for inter- and intra-layer excitons. (f) Absolute circular polarization degree,  $|P_c| = \frac{|I^+ - I^-|}{|I^+ + I^-|}$ , where I<sup>+</sup> (I<sup>-</sup>) indicates co-(cross)-polarized PL component intensity for IX under gate voltage (V<sub>g</sub>) sweep. The interlayer hysteresis is caused by change in valley-depolarization times caused by electron/hole doping. (g) Time dependent IX emission characteristics. The PL intensity corresponding to IX<sup>S</sup> and IX<sup>T</sup> at 1.40 eV and 1.42 eV can be used as bits 0 and 1 respectively. Writing and erasing voltages last for 3 min, while reading lasts for 64 min. Reprinted with permission from ref. 223, Copyright 2022 Springer Nature Limited.

the resulting photonic bands would have nontrivial topological invariants. A major source of loss in optical devices that significantly hinders large-scale optical integration in ordinary waveguides is back-scattering.<sup>205</sup> On the other hand, topologically protected waveguides are unidirectional, transmitting electromagnetic waves without back reflection even in the presence of disorder. Topological transport in photonics has unprecedented applications in designing unique devices with immunity to performance degradation due to disorder or outside environment.<sup>228–230</sup>

First photonic analogue of QHE was realized by Wang *et al.*<sup>231</sup> A 2D square lattice photonic crystal was prepared using gyromagnetic ferrite rods as shown in Fig. 12(a). The structure was sandwiched between two metallic layers to provide confinement in z-direction. Under the application of magnetic field of magnitude 0.2 T, a gap is opened between two topologically non-trivial bands which is depicted in Fig. 12(b) with a gapless forward moving edge state. Numerical simulation [Fig. 12(c)] showed the unidirectionality and immunity to disorder of waveguide at frequency 4.5 GHz which falls

within the non-trivial gap. Experimental transmission data confirmed a very low backscattering of this waveguide as shown in Fig. 12(d). Such single mode one-way waveguides have allowed for the novel design of devices for tunable delays and phase shifts with unity transmission,<sup>232</sup> reflectionless waveguide bends and splitters,<sup>233</sup> signal switches,<sup>234</sup> directional filters,<sup>235,236</sup> broadband circulators,<sup>237</sup> and slow-light waveguides.<sup>238</sup> A challenge in this direction though has been a weak magnetic response at optical frequencies.

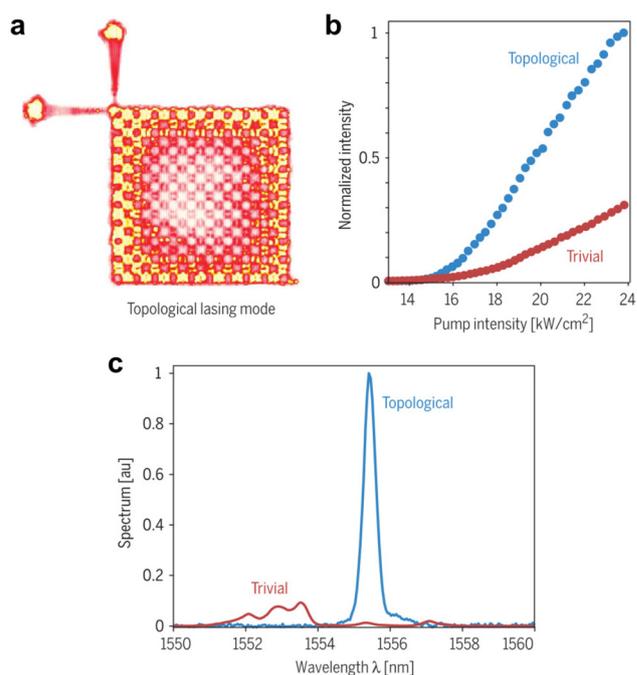

Further investigation into the implementation of such models in optical domain led to several ideas to realize photonic topological materials, for example, using polarization of photons as pseudospin in photonic crystals,<sup>231,232,239</sup> coupled resonators,<sup>229,230,240</sup> or bianisotropic metamaterials.<sup>228</sup> Subsequently, first photonic TI was introduced in 2013<sup>241</sup> where an array of coupled helical waveguide arranged in a honeycomb lattice led to the topological protection of photon transport realized using periodic modulation inspired by Floquet TIs. Around the same time, an aperiodic coupled ring resonator was also realized experimentally which showed topo-

**Fig. 12** First experimental demonstration of the topological protection in photonic crystals at microwave frequencies.<sup>231</sup> (a) Gyromagnetic photonic crystal slab with ferrite rods represented by blue dots arranged in a 2D square lattice arrangement. Due to confinement in *z*-direction by metallic plates this creates 2D transverse magnetic (TM) mode. logically protected photon modes.<sup>240</sup> Since then, there have been many proposals<sup>207,242–252</sup> both experimental and theoretical to realize a photonic analogue of a solid-state TI.

A vital application of photonic TI is a topological insulator laser which was realized recently.<sup>253,254</sup> The idea was to use an array of coupled ring resonators phase shifted amongst each other to mimic the effect of imaginary hopping strength in a square lattice [Fig. 13(a)]. The outer perimeter was pumped to promote lasing while inner region had losses. They showed that this topological insulator laser lased in a single mode while a trivial laser showed multi-mode operation [Fig. 13(b)]. The non-trivial laser also had a much higher slope efficiency even in the presence of defects as shown in Fig. 13(c). A recent theoretical work showed that indeed the coherence of laser emitters is greatly improved by a topological design.<sup>255</sup> This major breakthrough has been recognized by many groups to realize more TI lasers<sup>256–258</sup> and move towards a mode-locked pulsed laser,<sup>259</sup> a challenge for last few decades. Moreover, recently valleytronic properties have also been realized using topological photonics which finds applications in on-chip communications,<sup>260</sup> and quantum cascade lasers.<sup>256</sup>

### 4.3 Plasmonics and photodetection

Surface plasmon polaritons (referred simply as plasmons) are quanta of elementary excitation that involve collective oscillations of electrons.<sup>204,261,262</sup> These charge oscillations are usually confined to the surface of 3D metallic material interfaced with air.<sup>204,261,262</sup> In case of TIs, the situation is slightly different due to the presence of a 2D topologically protected surface state sandwiched between two insulators: topological bulk and air.

TI surface states host Dirac plasmon with a plasmon mode dispersion given by,<sup>204,263,264</sup>

$$\omega_p = \sqrt{\frac{D}{\epsilon_0 \epsilon}} q \quad (1)$$

where  $D$  is the Drude weight, and  $\epsilon$  is the effective relative dielectric constant. For TI,  $D = \frac{e^2 v_F}{\hbar} \sqrt{\frac{n}{4\pi}}$ , very similar to graphene<sup>265</sup> due to a similar relevant charge response and presence of Dirac carriers. Dirac plasmons have been experimentally observed in TIs<sup>266–270</sup> and form one of the major TI device applications for photodetection, especially in the terahertz regime in a field-effect transistor.<sup>271–273</sup> This resonant plasma-wave photodetection in case of TI has been shown to be more efficient than in case of graphene.<sup>274</sup> The utilization and integration of these Dirac plasmons in current Si-based electronic devices was theoretically proposed a few years

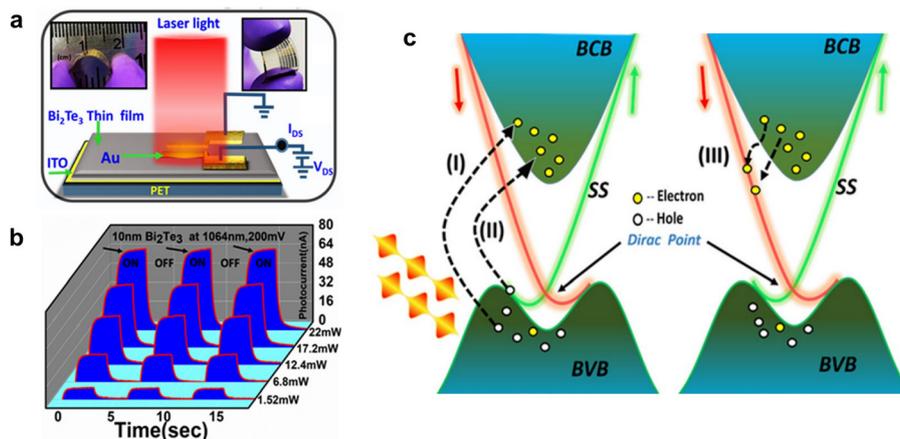

**Fig. 14** Si-based terahertz plasmonic device. (a) Schematic of Si-(111) with  $1/3$  monolayer Br coverage in a  $\sqrt{3} \times \sqrt{3}R30^\circ$  supercell. This uniform configuration has the least energy compared with random and cluster configurations. (b) Comparison of band structure obtained using tight-binding (TB) approximation and density functional theory calculation with Perdew–Burke–Ernzerhof (PBE) and Heyd–Scuseria–Ernzerhof (HSE) functionals. (c) and (d) EELS of hole-doped Dirac bands at Fermi energy  $-0.1$  eV in  $q_x$  and  $q_y$  directions respectively to illustrate the anisotropy due to Dirac bands in the superstructure. The open black circles are fitted to  $\omega = \alpha\sqrt{q}$  with  $\alpha = 0.35$ , and  $0.345$  eV  $\text{\AA}^{-1/2}$  for (c) and (d) respectively. (e) 2D momentum space plots of EELS at various excitation energies clearly indicating the elliptical plasmonic dispersion. Reprinted with permission from ref. 275, Copyright 2015 American Physical Society.

back.<sup>275</sup> Using first-principles calculations it was shown that a  $1/3$  monolayer Br coverage on Si-(1,1,1) surface saturates the dangling bonds and forms a uniform  $\sqrt{3} \times \sqrt{3}R30^\circ$  honeycomb superstructure [Fig. 14(a)] which generates anisotropic

Dirac bands near Fermi level [Fig. 14(b)]. The plasmonic properties of these bands were illustrated by broadened peaks of electron energy loss spectrum (EELS) as shown in Fig. 14(c). The anisotropy of Dirac bands leads to an elliptical dispersion of plasmons which can still be fitted with to the  $\sqrt{q}$  relationship in eqn (1). Moreover, these Dirac surface states can be protected by using a large-gap 2D material, for example, Boron Nitride, as a protective layer to make such Si-based devices robust.<sup>275</sup>

A disadvantage of plasmons is their dispersion dependence on carried density ( $n$ ). Although this dependence allows for gate-voltage tunability, it hinders applications that require a stable excitation frequency in changeable environments,<sup>276</sup> leading to unfavorable device operating conditions, for example, low temperature limit, high quality sample requirement, and unstable operation.<sup>277</sup> Recently, a wide range of density dependence of plasmons have been found in topological semi-metals,<sup>278,279</sup> even though they have similar linear electronic dispersion to graphene. Interestingly, there's a possibility of anomalous density independent plasmons (DIP) in 1D carbon nanotubes,<sup>280</sup> and nodal surface of electrides.<sup>276</sup> A unified theory of  $n$ -independent plasmons was developed recently by Wang *et al.*<sup>277</sup> DIPs can fundamentally overcome terahertz-unstable bottlenecks in conventional devices and have been proposed for broadband terahertz spectroscopy in 2D nodal line semi-metallic metamaterials.<sup>277</sup>

A unique feature of TI surface state is spin-momentum locking.<sup>7,281</sup> Zhang *et al.*<sup>282</sup> demonstrated theoretically for a helical metal that a density fluctuation can induce a transverse spin fluctuation and *vice versa* leading to a spin-plasmon mode. These modes are expected to have a considerably higher lifetime<sup>283</sup> and hence are attractive for device applications<sup>283</sup> like spin-torque oscillators, yet to be observed experimentally.<sup>284</sup> TIs are also known to have non-linear optical properties and enhanced absorbance due to presence of topologically protected gapless surface state<sup>285</sup> and have been reported

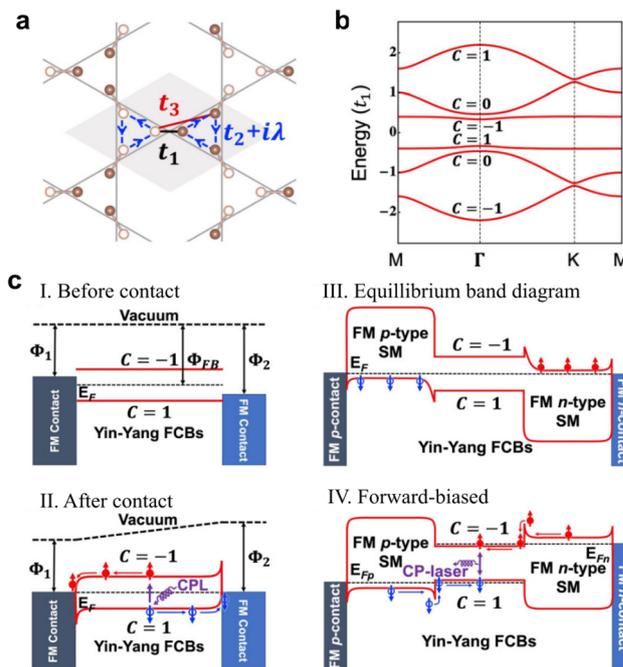

**Fig. 15** TI based flexible photodetector. (a) Schematic of photodetector device. Inset shows the flexibility of TI thin film. (b) Power dependent photocurrent response of flexible TI. to exhibit broad spectrum photodetection.<sup>286–290</sup> Recently, with a growing interest<sup>291–293</sup> in flexible optoelectronics given their potential applications in wearable devices, sensors, and communication,<sup>291–295</sup> a TI based flexible photodetector has been fabricated by depositing thin films of Bi<sub>2</sub>Te<sub>3</sub>, a well-known TI<sup>17</sup> onto a flexible plastic substrate, PET (polyethylene terephthalate).<sup>296</sup> Fig. 15(a) shows the schematic of photodetector device and the flexibility of deposited film. The photocurrent response for near infrared regime is shown in Fig. 15(b). As can be seen clearly the device detects the on and off laser mode. This high photo-response is speculated to be due to the band transitions and electron-pair generation between valence bulk band and conduction surface band as depicted in Fig. 15(c), but no certain theoretical or experimental evidence has been reported yet.

#### 4.4 Topological flat bands

Analogous to Haldane's proposal for integer quantum Hall effect, Fractional Chern Insulators have been proposed and numerically shown to be stabilized in topological FBs.<sup>39,297–301</sup> These FBs are counterpart of Landau Levels (LLs) of 2D free electron gas, with Chern number equal to 1, and arise due to the destructive interference of Bloch waves in a lattice system. This interference manifests itself into compact localized states in real space giving FBs macroscopic degeneracy, similar to LLs.<sup>11,37</sup> The infinite effective mass of carriers and hence their quenched kinetic energy in FBs allow the interactions to dominate leading to the stabilization of a variety of interaction-mediated exotic phases, such as Wigner crystallization,<sup>45,302</sup> high temperature superconductivity,<sup>47,303</sup> ferromagnetism,<sup>304–309</sup> Mottness,<sup>24,25</sup> Fractional QHE,<sup>38,310–312</sup> excitonic BEC<sup>53</sup> and TIs.<sup>313–320</sup>

A most widely used FB electronic lattice is a 2D Kagome lattice.<sup>310,321–324</sup> Depending on the sign of hopping integral within nearest-neighbor TB framework, this lattice hosts a FB either on the top or the bottom of the energy spectrum.<sup>310,322</sup> Recently, as an extension of Kagome lattice, a novel 2D lattice was introduced, called diatomic Kagome lattice<sup>325–327</sup> [Fig. 16(a)] containing two sets of Kagome bands. There is a rich phase diagram of band structures possible for this lattice in the parameter space of hopping integrals.<sup>326</sup> An intriguing band structure arises for certain hopping parameters which gives rise to enantiomorphic, *i.e.*, yin-yang FBs.<sup>326,327</sup> Under this configuration of bands, the FBs of the two sets of Kagome bands face each other forming the valence and conduction bands, both topologically non-trivial and flat but with opposite Chern numbers due to opposite effective signs of hopping integrals for the two sets. This fascinating band structure, called the yin-yang bands [Fig. 16(b)], constituting a new class of “quantum semiconductors”. It has been shown to exist in material systems, like anilato-based metal–organic frameworks,<sup>325</sup> superatomic graphene<sup>50,327</sup> and bilayer nickel-bis(dithiolene)<sup>327</sup> based on density functional theory calculations, while the superatomic graphene has been recently already made experimentally.<sup>54</sup> Interestingly, this unique band structure is speculated to show unconventional and exotic physics

**Fig. 16** (a) The diatomic Kagome lattice structure, where  $t_1$ ,  $t_2$ , and  $t_3$  are hopping integrals and  $\lambda$  represents the SOC strength. (b) The ideal yin-yang Kagome band structure and Chern numbers of each band with SOC. (c) Schematic band diagrams of two flat bands device setups. I. The band diagrams of the yin-yang FCBs and two ferromagnetic (FM) metal contacts with different work functions  $\Phi_{1,2}$  before contact in a photovoltaic cell. The Chern numbers are opposite for yin and yang FCBs. II. The band diagram after contact. A  $\sigma +$  CPL excitation creates a spin-up electron in the top yang FCB and leave behind a spin-down hole in the bottom yin FCB. The electron (hole) flows to the left (right) FM contact with a smaller (larger) work function. III. The equilibrium band diagram of a spin-polarized double heterostructure made of a FM p contact/FM p-type semiconductor (SM)/yin-yang FCB material/FM n-type SM/FM n contact. The Fermi level  $E_F$  is constant across the junction. IV. The band diagram after a forward bias applied to III. where the spin-up electrons and spin-down holes are injected into yang and yin FCBs, respectively, and the electron–hole recombination emits a CP laser.  $E_{Fn}$  ( $E_{Fp}$ ) represents the quasi-Fermi level of electrons (holes). Reprinted with permission from ref. 326, Copyright 2020 American Physical Society.

like, giant circular dichroism (CD),<sup>326</sup> anomalous excitonic behavior,<sup>50,53</sup> and topological superconductivity.<sup>328</sup>

Unconventional optical properties of yin-yang bands provide a perfect platform for topological FB optoelectronic device applications. The stabilization of a triplet excitonic insulator state<sup>50</sup> suggest the possibility of a complete population inversion between these bands, a property crucial for the realization of a solid-state laser. In addition, due to a flat conduction and valence band the coherence in wavefunction is naturally present which makes it an ideal candidate for a single mode cavity-free ultralow threshold laser. Two proposals for FB devices based on yin-yang bands were given by Zhou *et al.*<sup>326</sup> and are elaborated here in Fig. 16(c). Interestingly, yin-yang FBs allow for the possibility of quantization of photo-excited FB Hall conductivity.<sup>327</sup> One can take advantage of this

quantization to build robust topological photodetectors in a photovoltaic cell, as illustrated in Fig. 16(c)I and 16(c)II. Also, the flat Chern bands in whole Brillouin zone contribute to the CD effect in one chirality without the need to select one of the two sets of valleys, as in valleytronics,<sup>210</sup> whose CD effects would cancel out each other. This will enable to build CP lasers in a heterojunction diode, as illustrated in Fig. 16(c)III and 16(c)IV.

## 5. Summary and outlook

In this review, we have presented a concise updated review on device technologies utilizing unique spin, electronic, and optical properties of topological materials. The guiding principle behind this review has been to illustrate the unique physical properties of topological materials and define their critical role in the development of new spintronic, electronic, and optical quantum device technologies. In topological spintronic devices, several novel approaches to achieve high spin-polarization current have been elaborated in various systems *e.g.*, curved 2D TIs through strain engineering, heterostructures based on TI and FM, traditional semiconductors, 2D transition metal dichalcogenides with topological 1D dislocations, and 2D materials with non-centrosymmetric symmetry. In topological electronic devices, the aspiring exploration of different topological materials based on distinct physical mechanisms in field effect transistors has been retrospectively followed by a concise review of topological p–n junctions and recent proposals of other topological electronic devices. In topological optoelectronic devices, recent progress of the topological photodetector and topological laser have been briefly reviewed based on the formation of topological plasmon polaritons and photonic TIs, respectively. At last, an intriguing and exciting novel topological yin-yang flat-bands system is illustrated in detail for its promising applications in topological optoelectronics.

With the fast development of topological materials, their applications in various fields have been broadly explored. The progress in all these fields is inspiring, and one of the most promising applications of topological materials has been well recognized in the field of magnetic devices, *i.e.*, topological spintronics, due to their outstanding spin-to-charge and charge-to-spin interconversion that arises from their topological nature. We can anticipate the emergence of a series novel magnetic device based on topological materials in the near future. On the other hand, the studies of topological electronic and optoelectronic devices are awaiting some essential breakthroughs, especially in the experimental perspective, to compete with the current mature technology based on traditional electronic and optoelectronic materials. Yet, they may supplement the current technologies in some special targeted applications. The study of topological materials has spawned a much more collaborative community that has united researchers from various fields, which will surely facilitate exploration of topological materials in technologies beyond what have

been covered here. New applications based on novel topological materials will remain one of the most attractive research fields in the near future.
